The Meaning of ‘Most’: semantics, numerosity, and psychology

Paul Pietroski, Jeffrey Lidz, Tim Hunter, and Justin Halberda*

Abstract: The meaning of ‘most’ can be described in many ways. We offer a framework for distinguishing semantic descriptions, interpreted as psychological hypotheses that go beyond claims about sentential truth conditions, and an experiment that tells against an attractive idea: ‘most’ is understood in terms of one-to-one correspondence. Adults evaluated ‘Most of the dots are yellow’, as true or false, on many trials in which yellow dots and blue dots were displayed for 200ms. Displays manipulated the ease of using a “one-to-one with remainder” strategy, and a strategy of using the Approximate Number System to compare of (approximations of) cardinalities. Interpreting such data requires care, in thinking about how meaning is related to verification. But the results suggest that ‘most’ is understood in terms of cardinality comparison, even when counting is impossible.

* All authors contributed equally to this work, which has benefited from the comments of audiences at the University of Pennsylvania, the Hopkins Workshop on Language, Harvard University, SALT 18, and the Linguistic Society of America annual meeting. How is the word ‘most’ related to human capacities for detecting and comparing numerosities? One might think the answer is obvious, and explicit in standard semantic theories: ‘most’ is understood in terms of a capacity to compare cardinal numbers; e.g., ‘Most of the dots are yellow’ means that the number of yellow dots is greater than the number of nonyellow dots. But there are other possibilities for how competent speakers understand ‘most’, and we offer experimental evidence that tells against some initially attractive hypotheses. By discussing one lexical item in this way, we hope to illustrate how semantics and psychology can and should be pursued in tandem, especially with regard to the capacities that let humans become numerate.

Following common practice in semantics, we begin by characterizing the contribution of ‘most’ to the truth conditions of sentences that have the following form: Most (of the) Δs are Ψ. At this level of analysis, there are many equivalent characterizations, as discussed below. Our aim is to give some of these formal distinctions empirical bite, in a way that permits adjudication of distinct hypotheses about how speakers understand ‘most’ (cp. Hackl [forthcoming]). In short, we want to know how speakers represent the truth conditions in question.

In section one, we focus on two ways of formally specifying a truth condition for ‘Most of the dots are yellow’: comparing abstract cardinalities (is the number of yellow dots greater than the number of nonyellow dots); or comparing dots in terms of one-to-one correspondence (can some but not all of the yellows be paired off with all the nonyellows). In section two, we discuss the relation of such specifications to understanding, in the context of questions about how meaning is related to verification. We contend that experimental evidence, of the sort we offer, can tell for/against certain hypotheses about how understanding. Section three extends this point via the distinction between algorithms and functions computed (Church 1941, Marr 1982) in the context of semantics; cp. Peacocke (1986).
The idea is that ‘most’ is associated with an effective procedure, which yields answers to yes/no questions of the form ‘Most Δs are Ψ?’, given ordered pairs of subprocedures that determine whether something is a Δ and whether something is a Ψ. From this perspective, to understand ‘most’ is to recognize it as an instruction to generate (a representation of) a certain algorithm whose outputs have a binary character (yes/no, truth/falsity). A thinker may often be unable to execute their ‘most’-algorithm and use it as a verification strategy; and there may often be better ways of answering the specific question at hand. But our claim is that in suitably controlled circumstances, the ‘most’-algorithm will be used as a default verification strategy. In this sense, we assume the algorithms in question are executable, at least sometimes.

Section four reviews independent evidence that humans have the cognitive resources needed to implement both cardinality-comparison algorithms, via approximate number representations, and correspondence algorithms for ‘most’. Section five summarizes the various possibilities, under discussion, for understanding ‘most’ and verifying sentences of the form ‘Most (of the) Δs are Ψ’. In section six, we present an experiment in which displays of dots varied across trials, in ways that made it easier or harder to employ a correspondence algorithm as a verification strategy. There was no evidence of subjects using such a strategy. By contrast, there was clear evidence of subjects of comparing cardinalities, via the Approximate Number System (ANS). In section seven, we discuss some potential concerns about the task. But detailed analysis confirms our conclusion that even when speakers are forced to estimate the relevant cardinalities, they understand ‘most’ in terms of whether one number is greater than another. Section eight offers some concluding remarks about the utility of pursuing semantic and psychological questions in tandem, especially in studies of logical vocabulary and how such words interface with the cognitive systems that allow humans to become numerate.
1. Background Semantics

In the display corresponding to Figure 1, most of the dots are yellow.

![Figure 1](image.png)

(In the grey-scale presentations used here, white corresponds to yellow, and black to blue. But we will speak of yellow and blue, the colors used in our experiment.) In the display, it is also true that the number of yellow dots is greater than the number of dots that are not yellow. And however many dots there are, necessarily, most of the dots are yellow if and only if (iff) the yellow dots outnumber the other dots. Indeed, this seems obvious. So one might propose that (1)

(1) Most of the dots are yellow

means just this: \( \# \{ x: \text{Dot}(x) \& \text{Yellow}(x) \} > \# \{ x: \text{Dot}(x) \& \neg \text{Yellow}(x) \} \); where ‘\#\{ ...\}’ indicates the cardinality of the set in question. In figure 1, \( \# \{ x: \text{Dot}(x) \& \text{Yellow}(x) \} = 5 \), while \( \# \{ x: \text{Dot}(x) \& \neg \text{Yellow}(x) \} = 2 \). So perhaps a sentence of the form ‘Most (of the) Δs are Ψ’ means that the number of Δs that are Ψ is greater than the number of Δs that are not Ψ. ¹

¹ Let us flag three potential complications. First, in the absence of salient dots, examples like ‘Most dots are yellow’ are naturally heard as generic—impling, roughly, that dots tend to be yellow. But when presented with a display like Figure 1, the context of evaluation is transparent. Second, in ordinary discourse, instances of ‘Most (of the) Δs
On this view, the determiner ‘most’ signifies a relation that one set can bear to another. This allows for a unified semantics of determiners—words like ‘every’ and ‘some’, which can combine with a noun and then a tensed predicate to form a complete sentence as in (2-4).²

\[
(2) \ [(\text{Every dot}) \ (\text{is yellow})] \\
(3) \ [(\text{Some dot}) \ (\text{is yellow})] \\
(4) \ [(\text{Five dots}) \ (\text{are yellow})]
\]

One can say that ‘every’ signifies the subset relation, and hence that (2) is true iff \(\{x: \text{Dot}(x)\} \subseteq \{x: \text{Yellow}(x)\}\). Likewise, one can say that ‘some’ signifies nonempty intersection, and hence that (3) is true iff \(\{x: \text{Dot}(x)\} \cap \{x: \text{Yellow}(x)\} \neq \emptyset\). But one can also describe the semantic contributions of ‘every’ and ‘some’ in terms of cardinalities: every \(\Delta\) is \(\Psi\) iff \(\#\{x: \Delta(x) \text{ & } \neg \Psi(x)\} = 0\); some \(\Delta\) is \(\Psi\) iff \(\#\{x: \Delta(x) \text{ & } \Psi(x)\} > 0\). From this perspective, ‘five’ is a special case of ‘some’, since (exactly) five \(\Delta\)s are \(\Psi\) iff \(\#\{x: \Delta(x) \text{ & } \Psi(x)\} = 5\). This invites the characterization of ‘most’ noted above: most \(\Delta\)s are \(\Psi\) iff \(\#\{x: \Delta(x) \text{ & } \Psi(x)\} > \#\{x: \Delta(x) \text{ & } \neg \Psi(x)\}\). But while these biconditionals may correctly and usefully describe the contributions of

---

² The noun ‘dots’ is the determiner’s \textit{internal} argument, while ‘are yellow’ is the \textit{external} argument—on the model of [Fido \textit{chased Garfield}], in which ‘Garfield’ and ‘Fido’ are the internal and external argument of the verb.
determiners to sentential truth conditions, psychological questions remain. In particular, what representations do competent speakers generate in understanding determiners?

Prima facie, a speaker can understand ‘every’ and ‘some’ without having a concept of zero, or any capacity to determine the cardinality of a set. It seems like overintellectualization to say that sentence (2) means that zero is the number of dots that are not yellow, or that (3) means that the set of yellow dots has a cardinality greater than zero. Indeed, one might describe the semantic roles of ‘every’ and ‘some’ in first-order terms, without reference to sets: every $\Delta$ is $\Psi$ iff $\forall x: \Delta x(\Psi x)$, some $\Delta$ is $\Psi$ iff $\exists x: \Delta x(\Psi x)$. We will not pursue this particular issue here. But analogous issues arise with regard to ‘most’.

Theorists can capture the truth-conditional contribution of ‘most’ without reference to numbers, by appealing instead to one-to-one correspondence. For the notions of cardinality and one-to-one correspondence are intimately related. The yellow dots and the blue dots have the same cardinality, as in each of the scenes depicted in Figure 2, iff the yellow dots correspond one-to-one with the blue dots.

![Figure 2](image)

More generally, the yellow dots and the blue dots have the same cardinality iff there is a function $F$ such that: for each yellow dot $x$, there is a blue dot $y$, such that $F(x) = y$ & $F(y) = x$. And this truism has a consequence worth noting.
A thinker might be able to determine that some things correspond one-to-one with some other things, and hence that the former are *equinumerous* with the latter, even if the thinker is unable to determine the shared cardinality in question. Consider, for example, Figure 2b. One need not know that there are four yellow dots, and four blue dots, in order to know that there are (exactly) as many yellow dots as blue dots. We return to the relevant generalization, often called “Hume’s Principle,” which captures an important truth about numbers.

\[
\text{(HP) } \#\{x: \Delta(x)\} = \#\{x: \Psi(x)\} \iff \text{OneToOne}\{\{x: \Delta(x)\}, \{x: \Psi(x)\}\}
\]

Tacit knowledge of this generalization, ranging over predicates $\Delta$ and $\Psi$, may play an important role in mature numerical competence.\(^3\) But for now, we just want to note that recognizing *equinumerosity* does not require a capacity to recognize, compare, and identify cardinalities.

Correlatively, a thinker might be able to recognize *nonequinumerosity*—and determine which of two collections has the greater cardinality—without being able to recognize, compare, and distinguish cardinalities. Counting is not required to determine if some things outnumber some other things. In each scene in Figure 3, there are more yellow dots than blue dots.

\(^3\) For discussion, see Wright (1983), Boolos (1998), and the essays in Demopolous (1994). At least prima facie, the left side of (HP) is an identity claim that logically implies the existence of at least one cardinal number, while the right side is a correspondence claim (concerning the elements of the sets in question) that does not logically imply the existence of any number. So while (HP) is in some sense obvious, it seems not to be a truth of *logic*; see also note 8 below.
One can see that this is so, and hence that most of the dots are yellow, without counting or otherwise figuring out the number of yellow dots. It suffices to note that *some but not all* of the yellow dots can be put in one-to-one correspondence with *all* of the blue dots.

Put another way, the yellow dots outnumber the blue dots—the set of yellows has a greater cardinality than the set of blues—iff a proper subset of the yellow dots has elements that correspond one-to-one with the (elements of the set of) blue dots. And theorists can define a second correspondence relation, OneToOne*, as shown below.

\[
\text{OneToOne*}(\{x: \Delta(x)\}, \{x: \Psi(x)\}) \text{ iff } \\
\text{for some set } s, s \subset \{x: \Delta(x)\} \& \text{OneToOne}[s, \{x: \Psi(x)\}]
\]

Then for cases involving finitely many things, the following generalization is correct.

\[
\text{GreaterThan}(\#\{x: \Delta(x)\}, \#\{x: \Psi(x)\}) \text{ iff OneToOne*}(\{x: \Delta(x)\}, \{x: \Psi(x)\})
\]

If we allow for infinite subsets in the definition of ‘OneToOne*, this generalization wrongly implies that the set of natural numbers has a greater cardinality than the set of even natural numbers. (There is a proper subset of the naturals—e.g., the evens—that corresponds one-to-one with the evens.) But this supports the point that counting is *not* required to determine if some things outnumber some other things. Moreover, a “OneToOnePlus” relation can be defined more cautiously, with a second clause that is otiose for finite domains.
OneToOnePlus[\{x: \Delta(x)\}, \{x: \Psi(x)\}] \iff

(i) for some set \(s, s \subset \{x: \Delta(x)\} \& \text{OneToOne}[s, \{x: \Psi(x)\}]\), and

(ii) \neg\text{OneToOne}[\{x: \Delta(x)\}, \{x: \Psi(x)\}]

Then the following generalization is correct.

GreaterThan[\#\{x: \Delta(x)\}, \#\{x: \Psi(x)\}] \iff \text{OneToOnePlus}[\{x: \Delta(x)\}, \{x: \Psi(x)\}]

So (5) is true iff \text{OneToOnePlus}[\{x: \text{Dot}(x) \& \text{Yellow}(x)\}, \{x: \text{Dot}(x) \& \neg\text{Yellow}(x)\}].

(5) Most dots are yellow

And to repeat, given finitely many dots, this condition is met iff for some proper subset \(s\) of the yellow dots, \text{OneToOne}[s, \{x: \text{Dot}(x) \& \neg\text{Yellow}(x)\}]

Perhaps, then, (5) is not \textit{understood as} a numeristic claim according to which \textit{one} cardinality \textit{exceeds} another. Though likewise, (5) may not be understood as a correspondence claim. Given formally distinct but truth-conditionally equivalent ways of describing the semantic contribution of ‘most’, one wants to know if there is a corresponding psychological distinction—and if so, how to characterize it in a theoretically useful way.

One possibility is that there is no fact of the matter to discern, much as there is no fact of the matter about whether temperatures should be measured in Fahrenheit or Centigrade; cp. Quine (1960), Davidson (1974). Perhaps describing the meaning of (5) in terms of cardinalities is just as good, and just as bad, as describing that meaning in terms of one-to-one correspondence.

Some distinctions are merely notational, or at least not psychologically significant. But another possibility is that the contrasting formal descriptions invite, in some way that needs to be made more explicit, psychological hypotheses that differ in plausibility.

In particular, one might think it is \textit{less} plausible that (5) is understood in terms of cardinalities. Competent speakers can reliably answer questions involving ‘most’ in situations
that preclude counting. Moreover, in other work, we have found that some children who seem to lack exact cardinality concepts still seem to understand ‘most’ appropriately (Halberda, Taing and Lidz, 2007). Such facts are not decisive. Adults may have various methods for verifying cardinality claims, when counting is impossible or not worth the bother; and children may lack full competence. But distinctions among truth-conditionally equivalent specifications can at least suggest different algorithms for determining the truth/falsity of (5). And one can hypothesize that competent speakers associate sentences like (5) with algorithms of a certain sort.

2. Meaning and Verification

For these purposes, let’s assume that understanding sentences of the form ‘Most Δs are Ψ’ requires (exercise of) a general capacity to represent the truth conditions of such sentences accurately and compositionally. The question here is whether such understanding requires something more, like a capacity to generate canonical specifications of the relevant truth conditions; where for any such sentence, a canonical specification corresponds to a certain effective procedure that yields conditional specifications of truth values, given decisions about how to classify things as Δs/not-Δs and Ψs/not-Ψs.

One could certainly invent a communication system in which the sound of (5)

(5) Most dots are yellow

indicates the truth condition that is indicated equally well by (5a) and (5b).

(5a) GreaterThan[#\{x: Dot(x) & Yellow(x)\}, #\{x: Dot(x) & ¬Yellow(x)\}]

(5b) OneToOnePlus[\{x: Dot(x) & Yellow(x)\}, \{x: Dot(x) & ¬Yellow(x)\}]
A competent user of the system might be free to represent this truth condition in any workable way, and express any such representation—regardless of format— with the sound of (5). But one could also invent a language in which this sound is, by stipulation, an instruction to generate a representation of the form shown in (5a). We think the natural phenomenon of understanding is psychologically demanding in this sense. But a canonical specification/procedure need not be used as a verification strategy (cp. Dummett 1973); see Horty (2007) for discussion.

A canonical specification/procedure is a way of computing a truth condition. And one can make a yes/no judgment concerning the truth condition computed—in Fregean mode, one can make a judgment about which truth value is the one conditionally specified—without executing the mode of composition in question. Given (5a) as a way of computing the truth condition of (5), one can employ many “methods” (or verification strategies) to make the corresponding yes/no judgment. Depending on one’s capacities and background beliefs/desires, one might: count and compare cardinalities; pair off dots and check for remainders; ask a friend; roll some dice; use one of these methods for a small sample of dots and extrapolate; or whatever.

Put another way, understanding (5) may be a matter of perceiving this sentence as one whose truth or falsity is specified in a certain way. But this is compatible with endlessly many strategies for judging whether the sentence is true. For even if one perceives (5) as posing the question indicated in (5a), as opposed to (5b), one might seek an answer in many ways.

The two procedures we focus on, cardinality-comparison and OneToOnePlus-assessment, can never disagree: there is no conceivable scenario in which these algorithms yield different results. Of course, actual attempts to execute the algorithms may fail in different ways in different circumstances. But taking the outputs to be conditional specifications of truth values, for any instance of ‘Most $\Delta$s are $\Psi$', the two procedures cannot ever yield specifications that
specify different truth values. Nonetheless, the “truth-procedures” differ. One can imagine creatures who cannot represent cardinalities, and so cannot associate (5) with the first procedure. Likewise, one can imagine creatures who lack the representational resources to associate (5) with the second procedure. One can also imagine creatures who have the cognitive resources required to associate (5) with either procedure, but in fact understand (5) in exactly one way, sometimes using the other procedure as a verification strategy.

Let us stress: our view is not that meaning is verification, or that studying verification strategies is a generally useful way to study meanings. We take it as given that whatever a declarative sentence means, there will be endlessly many ways of judging (in a given setting) whether or not the sentence is true. But we do find it plausible that at least with regard to “logical” vocabulary, meanings are individuated at least as finely as truth-procedures; see Church (1941) on sentential “functions-in-intension,” which can but need not be used as verification strategies.4 One way of vindicating this old idea is to independently describe situations that lead competent speakers to use meaning-specifying effective procedures as default verification strategies. If such situations can be empirically identified, this could also support (nondemonstrative but confirmable) inferences about meaning from facts about verification in these special situations.

Of course, there can be no guarantee that different speakers associate ‘most’ with the same canonical specification/procedure, or even that any one speaker does so across contexts.

4 Horty (2007), drawing on Dummett (1973), discusses the relation of algorithms/procedures to Frege’s notion of definition. See also Chomsky’s (1986) discussion of I-languages, with ‘I’ connoting intensional/procedural characterizations of functions. But in this context, intensions should not be identified with sets of possible worlds, as Church’s own (algorithm-focused) discussion makes clear.
But hypothesizing variation is not costless. And in any case, one can try to argue empirically that certain algorithms, including some that initially seem like plausible candidates, are not used in situations that positively invite their use. In these cases, if such there be, data concerning verification would be informative.

More importantly, experimental evidence may reveal the use of verification strategies that are at odds with certain hypotheses about canonical specifications/procedures, given independently confirmed models of the cognitive systems that support the strategies.

To foreshadow, imagine discovering that adults often rely on the Approximate Number System (ANS) in judging whether or not most of the dots are yellow. Independently attractive models of this system suggest that it has no representations for single individuals; rather, the ANS generates estimates of the cardinalities exhibited by one-or-more things. In which case, the meaning of ‘most’ must permit verification via a cardinality-estimating system that does not represent single individuals. This turns out to be a substantive constraint, as we’ll argue in section five, since understanding ‘most’ in terms of correspondence would require an mechanism for converting representations like (5b) into representations like (5a).

\[
\begin{align*}
(5a) & \quad \text{GreaterThan}\left[\#\{x: \text{Dot}(x) \& \text{Yellow}(x)\}, \#\{x: \text{Dot}(x) \& \neg \text{Yellow}(x)\}\right] \\
(5b) & \quad \text{OneToOnePlus}\left[\{x: \text{Dot}(x) \& \text{Yellow}(x)\}, \{x: \text{Dot}(x) \& \neg \text{Yellow}(x)\}\right]
\end{align*}
\]

3. Analogy to Marr

The analogy to Marr’s (1982) contrast, between Level One (computational) and Level Two (algorithmic) questions, is intended. Given a system that seems to be performing computations of some kind, theorists can distinguish Level One questions about what the system is computing
from Level Two questions about *how* the system is computing it. With regard to understanding sentences, this distinction has a familiar application that can be extended to understanding words.

Imagine three people, each with their own definition of ‘most’. Alex learned ‘most’ explicitly in terms of cardinalities and the arithmetic relation greater-than, while Bob (who cannot count) has always defined ‘most’ in terms of one-to-one correspondence. By contrast, Chris has an ANS that interacts with other cognitive mechanisms to generate ‘most’-judgments as follows: in cases that are *not* close calls, say 9 yellow dots versus 4 blue dots, Chris shares the judgments of Alex and Bob; but in close cases, say 8 versus 7, Chris cannot tell the difference and so defers to others. Alex, Bob, and Chris can communicate. Indeed, they never disagree about whether sentences of the form ‘Most Δs are Ψ’ are true. In this sense, they understand each other, at least in a Level One way. But their psychologies differ in important respects.

Given some assumptions about the kinds of sentential properties that competent speakers can recognize—say, the truth conditions of declarative sentences—one can ask *how* speakers recognize these properties. In practice, semanticists usually stop short of offering answers, even when they specify algorithms that determine truth conditions on the basis of hypothesized properties of words and modes of grammatical combination. Such algorithms are rarely put forward as explicit Level Two hypotheses.\(^5\) For often, it is hard enough to find *one* good way of characterizing a “composition function” that speakers *somehow* compute. But it is widely agreed that complex expressions are understood, one way or another, by employing algorithms that are compatible with constraints imposed by natural language syntax.

\(^5\) For an exception, see Larson and Segal (1995). Though of course, many would agree that semantics should be viewed as a branch of human psychology; see, e.g., Higginbotham (1985), Chierchia and McConell-Ginet (2000).
Similarly, one can and should distinguish the truth conditional contribution of a word like ‘most’ from how that contribution is represented by competent speakers. It is often useful to begin with a proposal about what the truth conditional contribution is; and for these initial purposes, truth conditionally equivalent representations are equivalent. The corresponding Level One task—of describing the contributions of determiners like ‘every’ and ‘most’ in a way that permits formulation of some algorithm that determines the truth conditions of relevant sentences, given relevant syntactic constraints—is far from trivial. But depending on the theorist’s choice of formal notation, it might be enough to say that each determiner indicates a certain function from pairs of predicates to truth conditions. In which case, endlessly many formally distinct lexical specifications will be acceptable. But if the task is to say how speakers understand words, with the aim of saying how linguistic comprehension frames the task of evaluating sentences, theorists must get beyond Level One questions about which function a given word indicates.

It may not be possible, at this early stage of inquiry, to formulate defensible Level Two hypotheses about exactly how speakers represent and compute any particular function. Still, one can try to formulate and defend “Level 1.5” hypotheses about the kinds of representations that children and adults employ in understanding the word ‘most’. Do they represent cardinalities, and a relation between them, or not? Of course, there is more than one cardinality-comparison algorithm; and there can be no guarantee that all speakers specify the meaning of ‘most’ in terms of “information flow;” see also Davies (1987) on the “mirror constraint.” But for our purposes, it is enough to contrast algorithms that require (representation and) comparison of cardinalities with algorithms that do not.

---

6 Peacocke (1986) introduces the “Level 1.5” terminology to talk about algorithms that correspond to a certain kind of “information flow;” see also Davies (1987) on the “mirror constraint.” But for our purposes, it is enough to contrast algorithms that require (representation and) comparison of cardinalities with algorithms that do not.
of the same one. But theorists can distinguish two classes of algorithms for determining whether or not most dots are yellow: algorithms which require representations of two cardinalities and a subprocedure for determining whether the first is greater than the second; and algorithms which require dot-representations that support a procedure for determining suitable correspondences (without needing to represent cardinalities).

Given this distinction, one can ask for each class of algorithms—i.e., for each abstract “way” of computing the relevant function—if there is some psychologically plausible way of computing the function in that (abstract) way. In this context, let us return to an earlier point. One might think that cardinality-comparison specifications/procedures are psychologically implausible. Independent evidence suggests that counting is often slower and more laborious than evaluating sentences with ‘most’. And in situations where items are presented too briefly to count, yet the subject can still determine whether or not most Δs are Ψs, appealing to a OneToOnePlus algorithm might seem especially attractive.

More generally, one might think that humans who cannot count understand ‘most’ in terms of correspondence as opposed to cardinalities. If this is correct, parsimony would suggest that adults who can count still understand ‘most’ in the same way. Perhaps counting provides a new way of determining whether some things (the Δs) bear the OneToOnePlus relation to some

7 The number of yellow dots might be determined by counting, or by recognizing a pattern already associated with a number. (One might come to associate a general spatial arrangement with a limited range of cardinalities—e.g., three items typically form some kind of triangle, two items a line—and thereby avoid counting as a method for assessing cardinalities; see Mandler & Shebo [1982], LeCorre & Carey [2007].) Counting might start with zero or one. A mechanism might determine whether one number is bigger than another by consulting memory, or by subtracting and checking for a (positive) remainder. And so on.
things (the Ψs). This suggestion coheres with certain foundational considerations that may well be germane to semantics and logic. Recall the generalization (HP),

\[(HP) \#\lbrace x: \Delta(x) \rbrace = \#\lbrace x: \Psi(x) \rbrace \iff \text{OneToOne}[\lbrace x: \Delta(x) \rbrace, \lbrace x: \Psi(x) \rbrace]\]

which reflects the deep relation between counting and one-to-one correspondence.

It turns out that all of arithmetic follows from (HP), given a consistent logic that is presupposed by any plausible semantics for natural language. This remarkable fact, essentially proved by Frege (1884, 1893, 1903), illustrates the power of the modern logic that Frege (1879) invented and contemporary semanticists regularly employ. Given this logic, (HP) encapsulates arithmetic. The intuitive simplicity of one-to-one correspondence, and its relation to the foundations of arithmetic, thus adds to the attractions of saying that ‘most’ (along with other counting/cardinality expressions) is understood in terms of one-to-one correspondence.

Given these considerations, one might expect speakers to jump at the chance of evaluating ‘Most dots are yellow’ without having to determine the number of yellow dots (and nonyellow dots). Anecdotally, this was the expectation of most semanticists and logicians we queried, including one or more authors of this paper. At a minimum, a OneToOnePlus strategy would seem to be a plausible candidate for speakers who (for whatever reason) cannot count the

---

8 The logic is second-order, permitting quantification into positions occupiable by predicates. But this cannot be foreign to a speaker who understand ‘most’; see note 2. Of course, deriving the (Dedekind-Peano) axioms of arithmetic from (HP) requires definitions for arithmetic terms, along with appeal to a first number; and see note 3. But Frege defined zero as the number of things satisfying a logically contradictory property, and then given (HP), was able to prove the following: zero has a unique successor, which has a unique successor, and so on; and these “descendants” of zero support proofs by (mathematical) induction. See Pietroski (2006) for the potentially broader relevance to linguistics.
relevant dots. Our experiment, described in section six, suggests that this strategy is not available to participants. But before turning to the details, we need to review some relevant literature concerning the psychology of number.

4. Background Psychology, Including The ANS

The two classes of algorithms we have been discussing, corresponding to (5a) and (5b),

(5a) GreaterThan[{\#x: Dot(x) & Yellow(x)}, {\#x: Dot(x) & ¬Yellow(x)}]
(5b) OneToOnePlus[{x: Dot(x) & Yellow(x)}, {x: Dot(x) & ¬Yellow(x)}]

involve two kinds of representational resources for which there is evidence in the psychological literature. In this sense, neither class of algorithms requires novel cognition. First, there are representations of exact cardinal values—available at least to adults who know the meanings of words like ‘seven’, ‘nine’ and ‘sixty’—that might support a cardinality specification/procedure for ‘most’ (Dehaene 1997). Second, demonstrations of object-tracking in infants (Wynn, 1992; Feigenson, 2005) have revealed a system that can detect one-to-one correspondences, at least in certain situations. We must also consider a third cognitive resource, the Approximate Number System, that can provide numerical content for certain representations. But we wanted to discuss this system separately, with the distinction between (5a) and (5b) in place, without prejudging questions about whether and how speakers can use the ANS to verify ‘most’-claims.

Before learning how to count, children have an approximate sense of the number of items in an array. Like many nonverbal animals, including rats and pigeons, human infants have an Approximate Number System (ANS): an evolutionarily ancient cognitive resource that generates representations of numerosity across multiple modalities (e.g. for sets of visual objects, auditory
beeps, and events such as jumps, presented either serially or in parallel). The ANS does not require explicit training with numerosity in order to develop, and the brain areas that support this system in humans and in other primates have been identified (for review see Feigenson, Dehaene & Spelke, 2004). The ANS generates representations of pluralities in ways that effectively order those pluralities according to cardinality—albeit stochastically, and within certain limits described by Weber’s Law (for review see Dehaene, 1997).

Weber’s Law, which applies to many kinds of representation (e.g. loudness, weight, brightness), states that discriminability depends on the ratio of relevant representational values. With respect to the ANS, 6 things are detectably different from 12 to the same extent that 60 things are detectably different from 120. In each case, the Weber Ratio is 2 (WR = larger set #/ smaller set #). If the absolute numeric difference between the comparison groups is maintained, but the numerosities are increased (e.g. from 6 vs 12 to 12 vs 18, with a constant difference of 6), discriminability will become poorer. This is the so-called size effect. There is also a distance effect. If the cardinality of one group is held constant while the other changes (e.g. from 6 vs 12 to 6 vs 18), discriminability increases with greater numeric distance between the cardinalities. Representations of the ANS also seem to be integrated with adult understanding of exact cardinalities, since reactions to questions that seem to be about cardinalities or numerals—e.g., ‘Is 67 bigger than 59’—also exhibit size and distance effects (for review see Dehaene, 1997).

It will be useful to consider a widely endorsed model of the representations generated by the ANS: each numerosity is mentally represented by a distribution of activation on an internal “number line” constituted by a range of possible ANS-representations that exhibit certain global properties. The distributions in question are inherently noisy, and they do not represent number exactly or discretely (e.g., Dehaene, 1997; Gallistel & Gelman, 2000). The mental number line
is often characterized as having linearly increasing means and linearly increasing standard deviation (Gallistel & Gelman, 2000), as in Figure 4. In this figure, numerosities are represented with Gaussian curves, with the discriminability of any two numerosities being a function of the overlap of the corresponding Gaussians: the more overlap, the poorer the discriminability. For example, the curves corresponding to 8 and 10 overlap more than the curves corresponding to 2 and 4. And notice that all the representations, even the first one, are Gaussian curves. In this model, the ANS has no discrete representation of unity; no curve represents one (or more) things as having a cardinality of exactly one.9 We return to this point.

---

9 Even the initial representations/curves of the ANS—those with the smallest standard deviations, indicated towards the left in figure 4—are not representations of precise cardinalities; although only rarely will the ANS fail to distinguish a scene with (exactly) two perceptible items from an otherwise similar scene with (exactly) one perceptible item. The mental number line might also be modelled as logarithmically organized with constant standard deviation. While this would change the look of the curves in Figure 4, they would remain Gaussian. Either format reflects the hallmark property of the ANS: discrimination of two quantities is a function of their ratio (Weber’s Law). Here we will assume the linear format, as it has traditionally been the more dominant model. But either model would be applicable to the simple discrimination task we rely on (e.g., Cordes et al., 2001; Gallistel & Gelman, 2000; Meck & Church, 1983, Whalen et al., 1999).
The acuity of the ANS improves during childhood. In terms of the model, the spread of Gaussian curves decreases with age. Adults can discriminate numerosities that differ by at least a 7:8 ratio (Halberda & Feigenson, 2007; Barth, 2003; van Oeffelen & Vos, 1982). But for 6 month old infants, numerosities must differ by at least a 1:2 ratio in order for discrimination to be accurate (Xu & Spelke, 2000). In both human adults (Halberda, Sires & Feigenson, 2006) and infants (Zosh, Halberda & Feigenson, 2007), the ANS is capable of generating numerosity estimates for up to three sets in parallel—enough for the apparent numerical content of a determiner like ‘most’, which might compare two cardinalities. The capacity for building multi-set representations in infants suggests the potential relevance of the ANS for supporting comparative determiners at the earliest ages of language learning.

By 5 years of age, in numerate cultures, representations of the ANS have been mapped onto the discrete number words (LeCorre & Carey, 2007). The ANS is activated anytime a numerate adult sees an Arabic numeral, hears or reads a number word or performs a mental operation on numbers such as subtraction (for review see Dehaene, 1997). The ANS generates representations of numerosity very rapidly. Imagine flashing an array of items (e.g., 25 yellow dots) for only 250 ms, too fast for explicit counting. The recording of single neurons—in the physiological analog of the ANS, in awake behaving monkeys who are shown such arrays—suggests that the ANS can generate a representation of the approximate number of items present within 150 ms of stimulus onset. That is, a representation/Gaussian of approximately 25 can be generated very quickly (Nieder & Miller, 2004). When shown such arrays, adults and children over 5 can produce a discrete numerical estimate (e.g., ‘about 20 yellow dots’). Over many trials,

---

10 Recall that ‘most’ is essentially comparative—most Δs are Ψ iff #{x: Δ(x) & Ψ(x)} > #{x: Δ(x) & ¬Ψ(x)}—in contrast with (firstorderizable) determiners like ‘every’.

21
the pattern of the numerical estimates given by adults and children will follow the same shape as
the Gaussian curves in Figure 4. For example, when shown many instances of 25 dots, ‘twenty-
five’ will be the most common answer; though participants will also sometimes say ‘twenty-
four’ or ‘twenty-six’, ‘twenty’ or ‘thirty’ (etc.), with the probability of saying a given number
word forming a smooth Gaussian curve centered on ‘twenty-five’. (Halberda et al, 2006; Le
Corre & Carey, 2007; Whalen, Gallistel & Gelman, 1999). This demonstrates that the
representations of the ANS can be mapped to discrete number words, and thereby discrete
cardinal values, albeit in a noisy and approximate way.

Let us return, now, to the meaning of ‘most’. As noted above, the ANS will not deliver a
representation of something as exactly one. This system does not generate a representation of
unity or any representation of a “minimal” difference between distinct cardinalities; cp. Leslie,
Gallistel, and Gelman (2008). If only for this reason, speakers cannot rely on the representations
of the ANS to implement a OneToOnePlus algorithm, for understanding or evaluation. While
these representations can be (and are) linked to cardinal number words, they do not provide the
notion of a unit that distinguishes one cardinality from the next. Given one-or-more yellow dots,
the ANS can represent “it-or-them” as oneish; and in principle, the yellow dot(s) so-represented
might be paired with some similarly represented blue dot(s), until only unrepresented yellows or
blues remain. Thus, one can imagine a “OneishToOneishPlus” algorithm. But as we’ll see, the
data suggest a very different use of the ANS.

Nonetheless, representations of the ANS do represent things, stochastically, as ordered in
a certain way that seems numerical. And these representations can be mapped onto discrete
number words. This suggests two possible ways of using ANS-representations: first, in a
canonical specification/procedure of the truth conditions for ‘most’-sentences, without any
independent appeal to (concepts of) cardinal numbers; or second, in a frequently used verification strategy that naturally interfaces with a meaning canonically specified in terms of cardinality comparison. The first possibility deserves extended discussion. But it also raises technical difficulties that go well beyond the scope of this paper. So here, we focus on the second option. Corresonspondingly, our subjects are adult speakers of English who have presumably linked the Gaussian approximate number representations to the discrete number words.

11 We would quickly be led into discussions of partial functions, vagueness, techniques of supervaluation, secondary qualities, uncertainties (of subjects and theorists) and the attending puzzles. One tempting idea is to introduce a metalanguage notion ‘Exceed(x, y)’, where the variables range over cardinal numbers—whatever they are, perhaps certain sets that exhibit the right structural relations—and ANS representation types, with the following: unlike any pair of distinct numbers, a pair of ANS representations that lie within some specified range of “unreliable discriminability” can be such that neither Exceeds the other, even if there is a sense in which the representations are stochastically ordered. At least in ideal conditions, each ANS representation will have a Mode(Mean/Median)-number: the likeliest (average/middle) number of things to trigger the representation. But one can define notions of indifference such that ANS-representations with different M-numbers are indifferent with regard to ‘Exceeds(x, y)’.

With enough technology, theorists might be able to represent the meaning of the word used by numerate adults (‘Most_numerate’) as a precisification of the meaning of an earlier word, ‘Most_innumerate’ that has the following characteristic: when most of the dots are yellow, and it is not a close call, ‘Most_innumerate of the dots are yellow’ is true; when it is false that most of the dots are yellow, and it is not a close call, ‘Most_innumerate of the dots are yellow’ is false; but sometimes, as when 51% or 49% of the dots are yellow, ‘most_innumerate of the dots are yellow’ is neither true nor false. But however one spells out the details, two basic questions will remain: does the metalanguage expression ‘Exceeds(x, y)’ indicate a total function from pairs number-like entities to truth values, so that the result is false when the values of ‘x’ and ‘y’ are indifferent ANS-representations; and how should theorists think about the relation of their invented metalanguage to the concepts of speakers? We cannot discuss such questions here, important though they are.
As a way of fleshing out this second possibility, of speakers using their ANS in verification, one might imagine a “numeralizing waystation”—perhaps restricted to speakers like our subjects—that associates ANS-representations with independent representations of exact cardinal values. For example, an ANS-representation that is usually triggered by pluralities of six (though sometimes five or seven) might be associated with a mental analog of ‘6’, while an ANS-representation usually triggered by pluralities of nine (though sometimes eight or ten, and occasionally seven or eleven) might be associated with a mental analog of ‘9’. Given some such waystation that interfaces between the ANS and other cognitive systems, ‘most’-sentences could be understood as in (5a) yet often verified (imperfectly) via the ANS.

5. Putting the Pieces Together

By way of summarizing to this point, let’s stipulate that the ‘most’-function (which may be applicable only to the count-noun cases we are considering), is a total function that can be characterized in many ways: GreaterThan[#{x: Δ(x) & Ψ(x)}, #{x: Δ(x) & ¬Ψ(x)}]; OneToOnePlus[{x: Δ(x) & Ψ(x)}, {x: Δ(x) & ¬Ψ(x)}]; etc. From an extensional (E-language) standpoint, these different ways of notating the ‘most’-function are just that: notational variants. But from an intensional (I-language) perspective, the different notational choices suggest various possibilities for canonical specifications/procedures in terms of which speakers understand ‘most’. Some of these possibilities are depicted in Figure 5.

Speakers who associate (the sound of) ‘most’ with the ‘most’-function might understand ‘Most of the dots are yellow’ as a claim that logically implies cardinalities, or as a less numerically loaded correspondence claim. Cardinalities can be determined by counting. But
another strategy is to generate ANS-representations that can be sent to a numeralizing waystation that associates such representations with mental analogs of written numerals. Positing such a waystation is indicated, in figure 5, with the box containing ‘#’.

We also note, for completeness, two possibilities that seem especially unlikely: given a psychologically realized version of Hume’s Principle, indicated with ‘ΨHP’, a thinker might understand ‘most’ in terms of cardinality but (whenever possible) verify by checking for OneToOnePlus correspondence—or conversely, understand ‘most’ in terms of OneToOnePlus but default to verifying by counting.12

This map of options invites the question of which, if any, can be discredited by experimental methods? We focused on the initially tempting hypothesis that ‘most’ is understood in terms of correspondence, in part because ruling out this class of possibilities would be a substantive kind of progress that is achievable with current methods. The basic idea is simple:

12 The latter seems especially implausible, and our experiment tells against the former. But this is not to say that such procedures are impossible for competent speakers (see note 11).
Step 1, present participants (at time scales that make counting impossible) with scenes in which it is easy to employ a OneToOnePlus strategy, and scenes in which it is hard to employ this strategy. If this variation does not affect participants’ accuracy in evaluating the sentence ‘Most of the dots are yellow’, that tells against the initially tempting hypothesis. Step 2, determine whether participants rely on the ANS to evaluate ‘most’ and if yes, consider the possible mappings from meanings to this system.

In our experiment, we presented competent adult English speakers with various arrays of yellow and blue dots. On each trial, the subject was required to say whether or not most of the dots were yellow. Arrays were flashed too quickly for exact counting to be possible (i.e. 200 ms), thus precluding any branch in Figure 5 with ‘count’ as the method of evaluation. Across trials, arrays varied how easy or hard it was to apply a OneToOnePlus strategy. A null result of this manipulation argues against a OneToOnePlus specification of what ‘most’ means. More strongly, we looked for positive evidence of participants relying on representations of the ANS. For as noted above, if such representations are invoked to answer a ‘most’-query, this suggests that the query was not understood as one whose answer is the answer determined by a OneToOnePlus algorithm. Participants were presented with varying ratios of yellow to blue dots. And so the hypothesis that ANS representations were used, in evaluating ‘most’-sentences, leads to a very specific set of predictions (garnered from the literature on the ANS and classic psychophysics) concerning how performance should vary as a function of ratio.

6. Experiment

We used a common visual identification paradigm to test how speakers understand ‘most’.
Method

Participants

Twelve naive adults with normal vision each received $5 for participation.

Materials and Apparatus

Each participant viewed 360 trials on an LCD screen (27.3 X 33.7 cm). Viewing distance was unconstrained, but averaged approximately 50 cm. The diameter of a typical dot subtended approximately 1 degree of visual angle from a viewing distance of 50 cm.

Design and Procedure

On each trial, participants saw a 200ms display containing dots of two colors (yellow and blue). Participants were asked to answer the question ‘Are most of the dots yellow?’ for each trial. The number of dots of each color varied between five and seventeen. Whether the yellow set or the blue set was larger (and hence, whether the correct answer was ‘yes’ or ‘no’) was randomized. Participants answered ‘yes’ or ‘no’ by pressing buttons on a keyboard.

Each trial came from one of nine “bins”, each characterised by a ratio. The first bin contained trials where the ratio of the smaller set to the larger set was close to 1:2; the second bin contained trials where the ratio was close to 2:3; and the remaining bins contained trials close to 3:4, 4:5, ..., 9:10. Each participant received ten trials in each bin for each of four conditions: Scattered Random, Scattered Pairs, Column Pairs Mixed and Column Pairs Sorted. The total number of trials for each participant was therefore 9 ratios x 4 conditions x 10 trials = 360. These were presented in randomized order.

On Scattered Random trials, all the dots (blue and yellow) were scattered randomly throughout the display. See Figure 6a. In each of the other three conditions, dots were displayed in some way intuitively amenable to a “one-to-one pair off” algorithm, with yellow dots and blue
dots occurring in pairs. On Scattered Pairs trials, every dot from the smaller set was displayed paired with (approximately four pixels away from) a dot from the larger set; the remaining dots from the larger set were scattered randomly. See Figure 6b. On Column Pairs Mixed trials, dots were arranged in a grid with two columns and n rows, where n is the size of the larger set. Each row had either one dot from each set, or a single dot from the larger set with the position (left column or right column) for each item being determined randomly for each row. See Figure 6c. On Column Pairs Sorted trials, dots were likewise arranged in two columns and n rows, but with all the yellow dots in one column and all the blue dots in the other. The smaller set of dots was grouped together from the top of its column, with no empty rows between dots, so that the display consisted essentially of two parallel lines of dots with side (yellow on left column or right column) determined randomly. See Figure 6d.

Figure 6
Half of the trials for each trial type for each ratio were “size-controlled:” while individual dot sizes varied, the size of the average blue dot was equal to the size of the average yellow dot, so the set with more dots would also have a larger total area on the screen (i.e. more blue pixels when more dots were blue). The other half of the trials were “area-controlled:” individual dot sizes varied, but the number of blue pixels was also the number of yellow pixels (i.e., smaller blue dots on average when more dots were blue). On both size-controlled and area-controlled trials, individual dot sizes were randomly varied by up to 35% of the set average. This discouraged the use of individual dot size as a proxy for number.

Results

Percent correct for each participant for each ratio was entered into a 4 Trial Type (Scattered Random, Scattered Pairs, Column Pairs Mixed, Column Pairs Sorted) X 2 Stimulus Type (size-controlled, area-controlled) X 9 Ratio Repeated Measures ANOVA. There was a significant effect of Ratio, as participants did better with easier ratios: $F (8, 72) = 13.811, p < .001$; a significant effect of Trial Type, as participants did better on Column Pairs Sorted trials: $F (3, 27) = 47.016, p < .001$; no effect of Stimulus Type, as participants did equally well on size-controlled and area-controlled trials: $F (1, 9) = 1.341, p = .277$; and a marginal Trial Type X Ratio interaction, as participants did better on difficult ratios on Column Pairs Sorted trials: $F (24, 216) = 1.432, p = .094$. Participants did equally well on size-controlled and area-controlled trials, indicating that they relied on the number of dots and not continuous variables such as area that are often confounded with number. Performance for each participant for each ratio was combined across Trial Type for further analyses.

Planned Repeated Measures ANOVAs compared performance pair-wise for each Trial Type. Performance on Scattered Random, Scattered Pairs, and Column Pairs Mixed all patterned
together with no significant differences, whereas performance on each of these conditions was significantly worse than that on Column Pairs Sorted trials. The F and p values for these comparisons are listed in Table 1. This pattern can also be seen in Figure 7. Contrary to what would be expected from use of a OneToOnePlus algorithm, performance on Scattered Random trials patterned with performance on Scattered Pairs and Column Pairs Mixed, with percent correct declining as a function of Ratio (\# of larger set/ \# of smaller set). Performance on Column Pairs Sorted trials remained at ceiling for all ratios tested, suggesting that a different process was used to verify ‘most’ on these trials.

If participants relied on the representations of the Approximate Number System to verify ‘most’ on Scattered Random, Scattered Pairs, and Column Pairs Mixed trials, performance on these trials should accord with a model of the psychophysics of this system. We rely on a classic psychophysical model that has been used by labs other than our own, indicating its acceptance in the literature (e.g., Pica et al., 2004). The average percent correct at each ratio across participants is modeled for each Trial Type as a function of increasing Ratio (larger set/smaller set, or n2/n1). Pairs of numerosities are represented as Gaussian random variables X2 and X1, with means n2 and n1, and standard deviations equal to the critical Weber fraction (w) * n. Subtracting the Gaussian for the smaller set from the larger returns a new Gaussian, with a mean of n2-n1 and a standard deviation of $\sqrt{n1^2+n2^2}$ (simply the difference of two Gaussian random variables). Correlatively, subtracting X2 from X1 returns a new Gaussian random variable that has a mean of n1-n2, and percent *correct* can be calculated from this Gaussian as the area under the curve that falls to the right of zero, computed as:

![Figure 7](image-url)
The one free parameter in this equation is the Weber Fraction (w). This parameter determines percent correct for every Weber Ratio (n2/n1). The mean of subject means for percent correct at each of the nine ratio bins, and the theoretically determined origin of the function—50% correct at Weber Ratio = 1, where the number of blue dots and yellow dots would in fact be identical—were fit using this psychophysical model. As can be seen in Figure 8, the fits for Scattered Random, Scattered Pairs, and Column Pairs Mixed trials fell directly on top of one another. Table 2 summarizes the R^2 values, the estimated Weber fraction, and the nearest whole-number translation of this fraction for each fit. These R^2 values suggest agreement between the psychophysical model of the ANS and participants’ performance in the most-task (R^2 values > .85). The Weber fraction on these trial types suggests that participants relied on the representations of the Approximate Number System to evaluate ‘most’.

\[
\frac{1}{2} \text{erfc} \left( \frac{n_1 - n_2}{\sqrt{2w} \sqrt{n_1^2 + n_2^2}} \right) \times 100
\]

Figure 8
The Weber fraction is expected to be approximately .14 for adults in number discrimination tasks and ‘more’-tasks (Pica et al, 2005), and to range from .14- to .35 in adults when participants are translating ANS representations into whole-number values (via a “numeralizing waystation”), measured as the coefficient of variance (Halberda, Sires & Feigenson, 2006; Whalen et al, 1999). Our estimate of a Weber fraction of approximately .3 for three trial types suggests that participants may be translating the representations of the ANS into whole number values via some numeralizing waystation before evaluating ‘most’-sentences. For example, when shown an array of 12 blue and 16 yellow dots, these subsets may activate corresponding ANS representations of numerosity; and these values may be translated into cardinal-number estimates, like ‘twelve’ and ‘sixteen’, for purposes of evaluation. Further work is needed to determine if this is the case.

For comparison, we also fit the data from Column Pairs Sorted trials using the same model of the psychophysics of the ANS. This is to allow a direct comparison to the other 3 trial types, and not to suggest that participants are actually relying on ANS representations on Column Pairs Sorted trials. As can be seen in Figure 8 and Table 2, this model returned a radically different fit for these data, suggesting a Weber fraction of .04 or a whole number ratio of 25:26. While participants rely on the representations of the ANS on Scattered Random, Scattered Pairs, and

Column Pairs Mixed trials, performance on Column Pairs Sorted trials suggests a different process altogether. In fact, the estimated Weber fraction on Column Pairs Sorted trials (Weber fraction = .04) is very similar to estimates (Weber fraction = .03) from the literature for human adults detecting the longer of two line segments (Coren, Ward & Enns, 1994). Displays for our Column Pairs Sorted trials were constructed such that there is a perfect correlation between the number of dots per subset and the overall length of the column. This means that participants could attend only the length of the column to reach their decision, ignoring however many dots it took to make the column, and translate their judgement of “longer blue column” into a “more blue dots than yellow dots” answer without error. So even on our Column Pairs Sorted trials, adults do not appear to be using a OneToOnePlus strategy for verification. Rather, they are using column length as a proxy for number (the perceptual “lines” created by the blue and yellow columns).\footnote{This notion of using column length as a proxy for number brings up issues of meaning versus verification again. While the correlation of number and column length in the present case empowers this type of verification procedure, we do not believe that the perceived line lengths are supplying numerical values to the ‘most’ algorithm. Rather, the correspondence of the ‘most’ algorithm and a separate ‘longer-line’ algorithm are recognized by the system and the subjects then simply performs the ‘longest-line’ algorithm and gives its answer as an answer for a most question.}

We manipulated the ease of applying a OneToOnePlus strategy across trial type and found no effect of this manipulation. But we found evidence that participants relied on the representations of the ANS, representations that cannot be used to implement a OneToOnePlus strategy. As discussed in the next section, these results suggest that (at least for numerate adults), the meaning of ‘most’ is not specified in terms of one-to-one correspondence. In the next section, we also consider some alternative diagnoses of our results, and a related further question: do English speaking adults understand ‘Most of the dots are yellow’ as consistent with ‘There is one
more yellow than nonyellow dot’, or does the ‘most’-claim imply that there are significantly more yellow dots than nonyellow dots?

7. Other Possibilities

One can speculate that ‘most’ is understood in terms of correspondence, but that our task constraints somehow precluded use of a OneToOnePlus algorithm. For several related reasons, we think this is unlikely.

In two follow-up experiments, we obtained evidence that 200ms is long enough for subjects to determine the color of “loner” dots in scenes where all the other dots formed yellow-blue pairs. We first confirmed that this was enough time to distinguish scenes with “scattered pairs” (as in figure 6b above), from scenes with randomly scattered dots (as in 6a). Each of 24 subjects saw 180 trials, 90 of each type, with the ratio of yellow to blue dots varying as in the initial experiment. The task was simply to classify the scenes, according to whether or not they exhibited yellow-blue pairs (along with some loner dots). In the second study, stimuli were limited to scenes with scattered pairs: a new group of 24 subjects saw 180 trials each; but every scene had some loner dots of a single color. The task was to find these extra dots, not paired with dots of the other color, and report their color. Performance was as depicted in Figure 9.
As suggested by the comparison with data from our initial experiment, subjects who had to determine the color of loner dots actually did better than subjects who had to determine whether most dots are yellow. For scenes with scattered pairs, the Weber Fraction in the main experiment was .33 (corresponding to a discriminability ratio of about 3:4), while the Weber Fraction was .11 (corresponding to a discriminability ratio of about 9:10) when the task was to report the color of loner dots. So at least for these scenes, using a OneToOnePlus algorithm would have led to good performance. But in the initial experiment, performance fit the ANS model quite tightly, with no symptoms of performance deteriorating for “non-pair-off” scenes.\(^\text{14}\)

\[\text{Figure 9}\]

---

\(^{14}\) One might say that subjects were unable to use a OneToOnePlus strategy for these scenes, and that this led them to adopt an ANS-based strategy for all scenes. But this begs the question: if ‘most’ is understood in correspondence terms, why didn’t subjects adopt a correspondence strategy, with a result of increased accuracy for pair-off cases and decreased accuracy for other cases? We see no reason for thinking that our stimuli would have led subjects who understand ‘most’ in terms of correspondence to abandon a correspondence strategy.
This suggests that subjects (i) have the capacities required to quickly deploy a OneToOnePlus algorithm, (ii) will use these capacities when the task is suitably described, but (iii) do not use these capacities when the task is to evaluate ‘Most of the dots are yellow’. This tells against hypotheses according to which the sentence is understood as a OneToOnePlus claim.\textsuperscript{15}

This highlights a fact that we want to stress. The main experiment itself tells against the hypothesis that ‘most’ is understood in terms of one-to-one correspondence. For whatever ‘most’ means, participants were clearly able to use their ANS system to evaluate the target sentence. This is striking, but not inexplicable, if ‘most’ is understood in terms of cardinality comparison. Independent evidence suggests that the ANS interfaces, somehow, with representations of precise cardinalities; and given a “waystation” of the sort described above, our data is easily

\textsuperscript{15} Interestingly, even in the follow-up studies, performance showed a ratio effect. We can imagine two diagnoses of this fact. One is for our imagined critic to shift gears, and say that 200ms is ample time to use a OneToOnePlus algorithm for all of our scenes: perhaps we didn’t make it hard enough to pair off dots in “random” scenes (like 6a); and perhaps our data from the initial experiment reflects the need, in that task, to find pairs and identify loners— with no real difference in difficulty across scenes with scattered dots. We cannot yet rule out this possibility. But we find it more plausible that the ANS is immediately providing subjects with information about numerosity that is hard to ignore: even when the task is simply to report the color of loner dots, subjects are estimating dot numerosities; and as the ratio of yellows to blues approaches unity, raising the corresponding uncertainty, subjects find it harder to commit to a judgment—e.g., that the loner dots are yellow—which directly implies that there are more dots of the color in question. That is, 200ms may not be enough time to override the ANS and adopt an alternative decision procedure that is more accurate in the case at hand. But then the OneToOnePlus hypothesis implies that speakers understand ‘most’ in terms of an algorithm that (i) cannot make use of relevant information that is made available immediately, but (ii) somehow leads to performance that matches the model of how subjects would perform if they used the information the ANS provides.
accommodated under a meaning for ‘most’ based in cardinalities. On the other hand, if ‘Most dots are yellow’ is understood as the claim that some of the yellow dots correspond one to one with all of the nonyellow dots, then participants must somehow evaluate this claim by using information provided by their ANS. But the only plausible “interfacing” mechanisms make the OneToOnePlus hypothesis unattractive.

Prima facie, this hypothesis requires a mind that can do the following in 200ms: generate a semantic representation of ‘Most dots are yellow’; generate (presumably in parallel) an ANS representation of the relevant scene; and then exploit some strategy for using the latter representation to answer the question posed by the former. This presumably requires two waystations: one to “convert” ANS information into a comparison of cardinalities (or perhaps fuzzy analogs); and another, effectively implementing one direction of (HP), to use the cardinality comparison as a way of answering the OneToOnePlus question posed by ‘Most dots are yellow’.

By itself, the ANS is of no use in evaluating claims concerning one-to-one correspondence, since ANS representations are not representations of particular entities. Approximations of collection-numerosities are useful, but not for determining whether each nonyellow dot has a corresponding yellow dot—at least not without a lot of extra cognitive apparatus. Moreover, if speakers can and do connect the lexical item ‘most’ to both the ANS system and something like tacit knowledge of (HP), that undercuts much of the motivation for analyzing ‘most’ in terms of one-to-one correspondence. For knowledge of (HP) will require knowledge of cardinalities which OneToOnePlus was supposed to avoid.

In response, one might say that participants do try to use a OneToOnePlus algorithm, but that their performance is error-prone at 200 ms. But this makes it mysterious why performance declines as a function of decreasing Ratio (i.e. as the number of yellow dots and blue dots
becomes closer performance declines). An errorless OneToOnePlus algorithm would not show this decrement in performance. But an error prone OneToOnePlus algorithm might accidentally use an individual dot to cancel out more than one competitor (e.g. using a dot twice), or fail to use a particular dot altogether. As the yellow dots and blue dots become closer in number, such errors would become increasingly relevant to performance, leading to decreasing accuracy. This correctly predicts decreasing performance as a function of decreasing Ratio. But as we shall see, it would still fail to account for a subtlety in the present data.

For any particular trial included in (say) the 3:4 ratio bin, the number of items included for a single color could vary from as few as 5 to as many as 16 items, so that one trial might include 6 yellow and 8 blue dots while another might contain 12 yellow and 16 blue dots. An error prone OneToOnePlus algorithm predicts a difference in performance between these two trials. Because the two possible errors described above for an error prone OneToOnePlus algorithm work in opposite directions (i.e. using a particular dot more than once and failing to use a particular dot at all), these errors would tend to cancel one another out stochastically, as the total number of dots in a display increases. That is, performance should be better on a 12 yellow versus 16 blue dots trial than on a 6 yellow versus 8 blue dots trial. More generally, use of an error prone OneToOnePlus procedure predicts an effect of increasing accuracy with increasing number of dots in the display when ratio is held constant (Cordes et al, 2001). We tested this prediction with a linear regression on subject means, with percent correct as the dependent variable, and Ratio and Total number of dots in the display as dependent variables. This analysis allows us to ask the following question: while controlling for any possible effects of Ratio, is there any evidence that participants did better as the Total number of dots in the display increased? Contrary to the predictions of an error prone OneToOnePlus algorithm we found a marginally significant result in the opposite direction: t
(367) = -1.952, \( p = .052 \), slope = -.365. Participants did slightly worse within each Ratio as the Total number of items in the display increased. This analysis shows no support for an error prone OneToOnePlus algorithm, and remains consistent with the hypothesis that participants relied on the stochastic representations of the ANS—especially given considerations about possible guessing in participants, or perceptual crowding, which might lead to the slight negative slope.\(^{16}\)

A related thought is that participants might understand ‘Most of the dots are yellow’ as implying that the number of yellow dots is significantly greater than the number of nonyellow dots. Perhaps ‘most’ imposes the more demanding requirement that there be significantly more yellow dots (by some measure of significance). On this view, a situation with 10 yellow dots and 9 blue dots (\( \approx 52\% \) yellow) might not make ‘Most of the dots are yellow’ true, even if situations with 14 yellow dots and 9 blue dots (\( \approx 60\% \) yellow) would. This hypothesis predicts a decrease in participants’ willingness to assent to ‘Most of the dots are yellow’ as Ratio decreases (i.e. as the ratio of yellow to nonyellow dots moves closer to 1:1), independent of whether the more

\(^{16}\) Because comparisons made in the ANS are ratio-dependent, the discriminability of 6 yellow versus 8 blue dots would match that for 12 yellow versus 16 blue dots. If subjects are relying on the ANS to evaluate ‘most’ then there should be no effect of the total number of items involved in a display and only an effect of the ratio between the two sets. Two possible reasons for the slight decrease in performance (i.e. a decrease of \(-.365\%\) per dot) as a function of increasing Total number of dots in the display are that increased dots led to increased perceptual crowding making it harder for the ANS to generate accurate estimates of numerosity or that increasing Total number of dots in the display led to an increased tendency for participants to randomly guess, as if participants felt that when there were many dots in the display the task was harder (a similar effect has been seen in other tasks that engage the ANS for purposes of speeded comparative judgements: Pica et al, 2004). Thus, the present analysis shows no evidence for an error prone OneToOne+ algorithm and remains consistent with the hypothesis that participants relied on the stochastic representations of the ANS.
demanding meaning is rooted in cardinalities or in OneToOnePlus. If participants understood ‘most’ in this way, our observed result of a decrease in performance with decreasing Ratio could not be taken as evidence against OneToOnePlus. But subtleties in the data reveal that participants did not behave as if they were computing the more demanding (“significantly more”) meaning. Rather, they behaved as if one extra yellow dot makes ‘Most of the dots are yellow’ true.

First, when participants had an easy way of determining that the cardinality of the yellow dots was greater than the cardinality of the nonyellow dots, they maintained that 10 yellow dots and 9 nonyellow dots was an instance of most dots being yellow. This was the case on the Column Pairs Sorted trials in our experiment, in which participants relied on the length of the sorted columns as a proxy for number (Figures 7 & 8). In 94% of the relevant trials, participants treated scenes with 10 yellow and 9 blue dots as scenes described by ‘Most of the dots are yellow’ (see the data point furthest to the left in Figures 7 & 8 for Column Pairs Sorted trials).

Second, on the other three trial types (Scattered Random, Scattered Pairs, and Column Pairs Mixed) performance accorded with a psychophysical model that predicts that a single extra yellow dot suffices for the truth of ‘Most of the dots are yellow’. Graphically, this can be seen in the fitted curves depicted in Figure 8: these curves do not cross the x-axis (chance performance) until a Ratio of 1. This model predicts that participants will tend to answer the test question affirmatively--though the tendency may be slight—for any detectable positively signed difference between the yellow and nonyellow dots, up to a Ratio of 1. So the best fit model of participants’ performance predicts that any situation with at least one more yellow than nonyellow dot is a situation in which ‘Most of the dots are yellow’ counts as true.

Moreover, if participants understood ‘most’ as implying significantly more (as opposed to at least one more), their accuracy should have systematically deviated from the model as Ratio
decreased. As the cardinality of the yellow dots became closer to the cardinality of the nonyellow dots, any participant who understood ‘most’ in the more demanding way should have refrained from assenting to ‘Most of the dots are yellow’ in a way not predicted by the model based on the less demanding meaning. So as the Ratio approaches 1, the model becomes a less accurate representation of anyone who understands ‘most’ as implying significantly more. To check for such deviation from the model, we calculated participant means for percent correct for each ratio bin across the three trial types (Scattered Random, Scattered Pairs, and Column Pairs Mixed). The signed deviations of these means from the psychophysics model are plotted in Figure 10.

Figure 10

Differences between percent correct and the psychophysics model were centered on zero and varied randomly from +6% to –6% with no tendency for these deviations to increase as Ratio moved closer to 1. This means that participants behaved in accord with the psychophysics model, according to which one extra yellow dot suffices (up to the stochastic limits of the ANS to detect this difference) for judging that most dots are yellow.
8. Summary and Concluding Remarks

In this paper, we have used psychophysical methods to adjudicate between hypotheses about ‘most’ that are equivalent by standard semantic tests. The meaning of ‘most’ can be described in terms of a relation (GreaterThan) that holds between the cardinalities of two sets, or in terms of a correspondence relation (OneToOnePlus) that holds between the individual elements of those sets. Because these characterizations are mathematically equivalent, there cannot be any situation that distinguishes them. So to determine which corresponds to the mental representations of competent speakers of English, one must find evidence that distinguishes hypotheses that are truth conditionally equivalent. In our view, the processes involved in evaluating a sentence with ‘most’ provide such evidence.

Our experimental data reveals two important points. First, despite our attempts to make evaluation of ‘Most dots are yellow’ easy given a OneToOnePlus meaning, we found no evidence that English speakers invoke algorithms that take advantage of one-to-one pairings of individuals in deciding whether a sentence using ‘most’ is true in a given situation. Second, and more positively, our data show that the Approximate Number System (ANS) is implicated in the algorithms used in computing the applicability of ‘most’.

Again, we grant that a OneToOnePlus strategy can be used to evaluate a ‘most’-claim in some settings. But subjects in our study did not use such a strategy. One might maintain that ‘most’ is still understood in terms of correspondence, but that for whatever reason, our trials did not invoke a OneToOnePlus algorithm. Given a specific proposal, specific further evidence—e.g., that subjects can quickly classify displays as “scattered” or not—will be relevant. But note that our second point argues against the general idea that ‘most’ is understood in terms of
correspondence. The ANS can be used to straightforwardly evaluate ‘Most of the dots are yellow’ only if this sentence is understood in terms of cardinality comparison. So if the sentence is understood in terms of correspondence, then given our positive result that participants relied on the ANS for evaluation, an initial OneToOnePlus representation would have to be transformed in order to make use of the ANS. But this would seem to require a psychological realization of (HP), along with a suitable capacity to represent cardinalities, thus undercutting the initial attractions of the idea ‘most’ is understood in terms of correspondence. If competent speakers can (i) represent the yellow dots as having a greater cardinality than the other dots, and (ii) use the ANS to estimate these cardinalities, why think they understand ‘most’ in terms of OneToOnePlus—and thus employ an evaluation procedure more complicated than the one we propose—absent specific empirical motivation?

In this sense, our second result is the more important. And as noted above, it is compatible with either of two scenarios. First, adults might represent the meaning of ‘most’ in terms of a comparison of magnitudes. Instead of (5a), perhaps a better meaning specification is (5a’);

\[
(5a) \quad \#\{x: \text{Dot}(x) \land \text{Yellow}(x)\} > \#\{x: \text{Dot}(x) \land \neg \text{Yellow}(x)\}
\]

\[
(5a’) \quad G\{x: \text{Dot}(x) \land \text{Yellow}(x)\} \triangleright G\{x: \text{Dot}(x) \land \neg \text{Yellow}(x)\}
\]

where ‘G’ signifies a mapping (not from sets to cardinal numbers, but rather) from sets to Gaussian curves, each of which has a mean and a standard deviation, and ‘\triangleright’ signifies a comparison (not of cardinal numbers, but rather) of Gaussians.

A second possibility is that (5a), interpreted standardly in terms of cardinal numbers, correctly represents the meaning of ‘most’—but estimates of relevant cardinalities are supplied online by the ANS. Further experiments will be required to determine which of these two possibilities obtains.
A related question is whether participants in our experiment were actually computing the meaning of the stimulus question (‘Are most of the dots yellow?’) on every trial, or whether they might have converted it into a question with the word ‘more’. Since each trial contained dots of exactly two colors, most of the dots were yellow iff there were more yellow dots than dots of the other color (blue). This is a serious issue. But note that our questions about ‘most’, and the related number-relevant representations, also apply to ‘more’ (i.e., ‘more’ might be understood as Cardinality-more or as OneToOnePlus-more). Our results stand as an important test of these representations, independent of whether participants interpreted the task as asking a ‘most’-question or a ‘more’-question. And in one sense, ‘most’ must be deeply related to ‘more’: most Δs are Ψs iff the Δs that are Ψs are more than the Δs that are not Ψs. But how do speakers understand the claim that there are more of these than those?

Does it mean that these have a greater cardinality than those, or that these correspond OneToOnePlus with those, or something else? To the best of our knowledge, these issues remain unsettled by the literature on ‘more’. That said, our participants did appear to engage the task as asking a ‘most’-question, and they did not report translating this into a ‘more’-question. In ongoing work, we examine whether performance (on ‘Are most of the dots yellow’) changes as a function of increasing the diversity of items in the contrast set—e.g. by presenting arrays with yellow, blue, green and red dots—since ‘more’-judgments and ‘most’-judgments can be teased apart in scenes with dots of several colors (Lidz, Hunter, Pietroski & Halberda, in prep.)

Finally, we want to stress that this kind of research, relating the cognitive science of number to the lexical semantics of natural language quantifiers, lets one ask questions about meaning that often go unaddressed for lack of relevant evidence. Every semanticist knows that for any given expression, there will be many truth-conditionally equivalent ways of describing its
meaning. Given such equivalences, choosing among alternatives requires appeal to other considerations, often concerning compositionality or theoretical parsimony. In the current case, we have argued that the evaluation procedures involved in understanding may provide some insight into the semantic representations themselves. And as we have argued, aspects of cognition that provide content for the linguistic system—in this case, the Approximate Number System—may place constraints on the representational vocabulary of the lexicon itself.
